FORECAST OF ATLANTIC SEASONAL HURRICANE ACTIVITY FOR 1987

By

William M. Gray

(This forecast is based on past and current research by the author at Colorado State University together with new April-May 1987 meteorological information)

Department of Atmospheric Science
Colorado State University
Fort Collins, CO 80523
(As of 28 May 1987)
DEFINITIONS

**Atlantic Basin** - The ocean area of the entire Atlantic including the Caribbean Sea and the Gulf of Mexico.

**Hurricane** - A tropical cyclone with sustained low level winds of 73 miles per hour (32 meters/s) or greater.

**Tropical Storm** - a tropical cyclone with maximum sustained winds between 39 (17 m/s) and 72 (31 m/s) miles per hour.

**Tropical Cyclone** - a large-scale circular flow occurring within the tropics and subtropics which has its stronger winds at low levels. This includes tropical storms, hurricanes, and other weaker rotating vortices.

**Hurricane Day** - any part of a day in which a tropical cyclone is observed or estimated to have hurricane intensity winds.

**Millibar** - (abbreviated mb). A measure of atmospheric pressure. Often used as a vertical height designator. 200 mb is at a level of about 12 kilometers, 30 mb at about 23 kilometers altitude. Monthly averages of surface pressure in the tropics show maximum seasonal summer variations of about ± 2 mb. These small pressure variations are associated with variations in seasonal hurricane activity. Average surface pressure is slightly over 1000 mb.

**El Nino** - (EN) - a 12-18 month period in which anomalously warm sea surface temperatures occur in the eastern half of the equatorial Pacific. Moderate or strong El Nino events occur irregularly. Their average frequency is about once every 5-6 years or so.

**QBO** - Quasi-Biennial Oscillation. These letters refer to stratospheric (20 to 35 km altitude) equatorial east to west or west to east zonal winds which have a period of about 26 to 30 months or roughly 2 years. They typically blow for 12-16 months from the east and then reverse themselves and blow 12-16 months from the west and then back to the east again.

**SLPA** - Sea Level Pressure Anomaly. Caribbean and Gulf of Mexico Sea Level Pressure Anomaly in the spring and early summer has an inverse correlation with late summer and early autumn hurricane activity. The lower the pressure the more likely there will be hurricane activity.

**ZWA** - Zonal Wind Anomaly. A measure of upper level (~ 200 mb or 12 km altitude) west to east wind strength. Positive values mean winds are stronger from the west or weaker from the east than normal.

ABSTRACT

This paper discusses the author's forecast of the amount of tropical cyclone activity which might be expected to occur in the Atlantic Ocean region (including the Caribbean Sea and the Gulf of Mexico) in 1987. This forecast is based on the author's previous and current research (Gray, 1983, 1984a, 1984b, 1987; Gray et al., 1987) which relates seasonal amount of Atlantic tropical cyclone activity to four factors: 1) the El Nino (EN); 2) the Quasi-Biennial Oscillation of equatorial stratospheric wind (QBO); 3) Caribbean Basin and Gulf of Mexico Sea-Level Pressure Anomaly (SLPA); and 4) lower latitude Caribbean Basin 200 mb zonal wind anomaly in June and July.

Information received by the author up to 28 May 1987 indicates that the 1987 hurricane season can be expected to have about 5 hurricanes, 8 total name storms of both hurricanes and tropical storms intensity, and about 20 hurricane days. This means that the 1987 Atlantic hurricane season can be expected to be a slightly below average season by the standards of the last 40 years but an average active hurricane season based on conditions of the last 17 years. Seasonal hurricane activity during 1947-1969 was higher than it has been since 1970.

This forecast will be updated on 1 August before the start of the most active part of the hurricane season. The updated 1 August forecast which will make use of June and July data should be more reliable.

This paper also gives a background description of the methodology of this objective forecast scheme and verification information on the author's forecasts for the 1984-1986 seasons.
1. Background

The Atlantic basin (including the Atlantic Ocean, Caribbean Sea and Gulf of Mexico) experiences a larger seasonal variability of tropical cyclone activity than any other global tropical cyclone basin. The number of hurricanes per season can be as high as 11 per season (as in 1950, 1916), 10 (1969, 1933), 9 (as in 1980, 1955), or as low as zero (as in 1914, 1907), 1 (as in 1919, 1905), or 2 (as in 1982, 1931, 1930, 1922, 1917, 1904). Until the last few years there has been no objective and very skillful method for indicating whether a coming hurricane season was going to be an active one or not. Recent and ongoing research by the author (Gray, 1983, 1984a, 1984b, 1987; Gray et al., 1987) indicates that there are four atmospheric parameters (out of a large number studied) which can be evaluated in spring and early summer and which are correlated with the following season’s tropical cyclone activity. If these four predictors are used in combination, then it is possible to explain about half or more of the seasonal variability in Atlantic hurricane activity on a statistical multi-year basis.

This paper will briefly discuss the nature of these four seasonal hurricane predictors and what these predictors indicate for the level of hurricane and tropical storm activity for the coming 1987 season.

This paper has been prepared for the professional meteorologist, the news media, and any interested layman.
2. Atmospheric Predictors of Atlantic Hurricane Activity

The four predictors are the El Niño (EN), the Equatorial Stratospheric Quasi-Biennial-Oscillation (QBO) of east-west or zonal wind, the Caribbean-Gulf of Mexico springtime and early summer Sea Level Pressure Anomaly (SLPA), and lower latitude Caribbean Basin springtime and early summer 200 mb zonal wind anomaly.

a. The El Niño

At irregular intervals of 3-8 years, sea surface temperatures over the central and eastern tropical Pacific Ocean rise to several degrees Celsius above average values, and remain so for 12-18 months. Associated with this phenomenon, named El Niño, are disruptions of worldwide weather patterns, particularly in the tropics and subtropics. One consequence of El Niño is reduced hurricane frequency in the Atlantic basin.

Strong or moderate El Niño events (as defined by Quinn et al., 1976) have occurred during 16 hurricane seasons of this century. One can compare the number of hurricanes, hurricane days, etc., occurring in each of these 16 El Niño years to the number of such events occurring during the other 71 non-El Niño years of this century. Figure 1 is a plot of the seasonal number of hurricane days for the years of 1900-1986 with strong and moderate El Niño years shown by the thick lines with a circle. It can be seen that in most years with strong or moderate El Ninos, hurricane activity as measured by the number of hurricane days is typically much less than in non-El Niño years. Of the 16 years of this century with the lowest number of hurricane days, 9 were strong or moderate El Niño years. Of the 22 years of this century with the largest number of hurricane days, not one was an El Niño year.
Fig. 1. Number of hurricane days (figure at top of lines) in El Nino/ non-El Nino years from 1900-1986.
This El Nino-Atlantic hurricane activity association is related to the anomalously strong westerly upper tropospheric (12 km height or 40,000 ft) wind patterns which typically become established over the Caribbean Sea and equatorial Atlantic Ocean during El Nino years. Such westerly wind patterns are known to inhibit hurricane activity.

b. Quasi-Biennial Oscillation (QBO)

With the beginning of systematic wind measurements in the tropical stratosphere in the early 1950's, an unusually long periodic reversal of equatorward winds at altitudes of 50-10 mb (20-35 km or 69,000-110,000 ft) was first detected.

These equatorial winds change from westerly to easterly and back again to westerly with a period of about two and one-half years. This wind reversal has been termed the Quasi-Biennial Oscillation (or QBO) by scientists who first studied it. This QBO stratospheric wind oscillation encompasses the globe and at individual stratospheric levels is present at all equatorial observing stations — see Fig. 2.

The direction of the stratospheric winds at 30 mb (23 km altitude) has a surprising correspondence with Atlantic hurricane activity. Hurricane activity as measured by the number of hurricane days is, in general, nearly twice as great when these stratospheric winds blow from a westerly direction in comparison to when they blow from an easterly
Fig. 2. Illustration of typical zonal wind conditions in the 20 to 25 km altitude layer in the tropics when QBO winds are from the west (top diagram) vs. those conditions when they blow from the east (bottom diagram). The climatological annual wind cycle has been removed from all wind values. (Adapted from Newell et al., 1974).
direction. Figure 3 shows the number of hurricane days per year from 1949 through 1986 by east and west wind category. Notice how the west wind seasons (dashed line) usually have a higher number of hurricane days than east wind cases (solid line). Disregarding El Nino years (which due to their strong suppressing effect bias the data set) the ratio of seasonal hurricane days for west wind vs. east wind cases is 33.0 to 17.8. Because these winds change so slowly over such a long period, it is possible to anticipate their direction for several months into the future.

Recent research by the author is showing that this association is likely related to the lower 60 to 80 mb (~18 to 20 km altitude) stratospheric zonal wind speeds which occur in QBO west as opposed to QBO east wind situations. New analysis shows that the hurricane's inner core circulation often extends well into the lower stratosphere. Lower stratospheric zonal winds at levels of 80 to 60 mb in QBO west wind seasons are considerably less from the east across the Atlantic tropical disturbances and hurricanes than in QBO east wind seasons. There is thus much less lower tropospheric ventilation across the tropical disturbance in west wind situations. Weaker ventilation is conducive to hurricane formation and more intense inner-core hurricane development. Similar 80 to 60 mb wind differences are not observed in the northwest Pacific or Australia-South Pacific regions. These other ocean basins do not show such a QBO associated tropical cyclone modulation.
Fig. 3. Relationship between 30 mb stratospheric wind direction and seasonal number of hurricane days from 1949-1986. Years with no observation are those in which the 30 mb zonal wind is changing direction or is very weak.
c. Caribbean Sea Level Pressure Anomaly (SLPA)

Although the influence of the QBO and El Nino events on hurricane frequency are of primary importance, the influences of springtime and early summer regional Sea Level Pressure Anomaly (SLPA) also exhibit a detectable and significant association with seasonal hurricane activity. SLPA acts to influence seasonal cyclone frequency by about one cyclone for every 0.4 mb of mean pre-season pressure anomaly. More hurricanes occur when pre-season springtime Caribbean pressure anomaly is lower than average and fewer storms occur when pressure is higher than average. Lower pressure is typically associated with higher sea surface temperature and vice versa. As discussed by Shapiro (1982) one can account for much of the seasonal variation of sea surface temperature through the pressure anomaly.

d. 200 mb Zonal Wind Anomaly (ZWA)

A study of hurricane frequency over the last 25 years shows that Atlantic hurricane activity in non-El Nino years is also associated with late spring and early summer upper tropospheric west to east zonal wind velocities at the low latitude Caribbean Sea stations of Balboa, C.Z. (9°N), San Andres (12.5°N), Curacao (12°N), Trinidad (10.5°N) and Barbados (13°N). Stronger than average 200 mb (12 km or 40,000 ft level) winds from the west are associated with fewer hurricanes. By contrast, hurricane activity is more prevalent when early summer 200 mb winds at these stations are weaker than average from the west or stronger than average from the east. It is only the June-July winds which are related to cyclone activity. April-May winds are not related. These winds are not used for the 1 June forecast but assist with the 1 August updated forecast.
e. Internal Correlation of EN, QBO, and SLPA Predictors

To try to better delineate the relationships between these combinations of predictors and seasonal hurricane activity a multiple linear regression analysis was made. It was found that a very low internal correlation exists between each of these predictors. This is very fortunate and is the basis of the forecast scheme to follow. These low internal correlations of predictors allow for a significant forecast improvement when all these predictors are used in combination.

f. The Rationale for Developing an Atlantic Seasonal Hurricane Activity Forecast

A forecast scheme using this QBO, EN, SLPA and ZWA information is based on the premise that:

1) the sign (east or west) of the QBO wind direction changes on such a long period (~ 14-17 months) and in such a uniform manner, that this wind direction can be extrapolated for 3 to 6 months into the future.

2) the oceanography-meteorological community is able to detect the presence and approximate intensity of an El Nino event by 1 June or 1 August at the latest.

3) information on the Caribbean Basin—Gulf of Mexico sea level pressure and 200 mb zonal winds for the four pre-hurricane months of April through July are readily available.

Figure 4 shows the average distribution of hurricane and tropical storm activity by calendar date for a 95 year period. Note that although the official start of the hurricane season is 1 June, the active part of the hurricane season does not begin in earnest until after the 1st of August.
Fig. 4. Number of tropical storms and hurricanes (open curve) and hurricanes (solid curve) observed on each day, May 1, 1886 through December 31, 1980 (from Neumann, et al., 1981).

3. Seasonal Hurricane Activity Forecast Methodology

Seasonal hurricane activity forecast equations have been developed from 37 years of dependent data as discussed in the author and his colleagues' previous papers (Gray, 1984b; Gray et al., 1987). Recent research has led to some small modification of these formulas. The following equations show how the prediction of the number of hurricanes per year, the number of hurricanes and tropical storms per year, and the number of hurricane days per year are made from QBO, EN, SLPA and ZWA information.

a. Number of Hurricanes

Equation (1) gives a simple formula to predict the seasonal number of hurricanes:
Correction Terms

\[
\left( \frac{\text{Predicted No. of Hurricanes per season}}{\text{Season}} \right) = \text{Ave.} + \frac{[(\text{QBO}_1 + \text{QBO}_2) + \text{EN} + \text{SLPA} + \text{ZWA}]}{\text{Season}}\quad (1)
\]

where

\[\text{QBO}_1 =\] 30 mb equatorial wind direction correction factor
- if westerly add one, if easterly subtract one.
Set to zero if zonal wind direction during the season is
in a change over phase from east to west or west to east.

\[\text{QBO}_2 =\] correction factor for change in 30 mb equatorial zonal
winds (u) during the hurricane season - if uniformly
increasing westerly (positive \(\partial u/\partial t\)) then add one, if
uniformly decreasing westerly (negative \(\partial u/\partial t\)) then
subtract one. Set to zero if there is a change of sign of
\(\partial u/\partial t\) during the season.

\[\text{EN} =\] El Nino influence. If present subtract two for a moderate
El Nino event, four for a strong El Nino event. Add one in
non-El Nino years if QBO winds are from the west otherwise
set to zero.

\[\text{SLPA} =\] average SLPA for April-May, from selective Caribbean-Gulf of
Mexico stations. Add one or two if SLPA is \(< -0.4\) mb
or \(< -0.8\) mb respectively. Subtract one or two if SLPA
is 0.4-0.8 mb or \(> 0.8\) mb respectively. Make no
correction for SLPA between -0.4 and 0.4 mb.

\[\text{ZWA} =\] Zonal Wind Anomaly at 200 mb (12 km) for five low
latitude upper air Caribbean stations. Valid for June
and July wind data only in non-El Nino years. Used only
to update the 1 August forecast. Not used for the 1 June
forecast. Forecast an additional hurricane if the mean
June-July zonal wind anomaly for these 5 stations is less
than -1 m/s. Decrease the hurricane forecast by one
if June-July zonal wind anomaly is greater than +1.
Make zero if anomaly is \(\leq +1\) m/s.

b. Number of Hurricanes and Tropical Storms

Equation (2), similar to Eq. 1 gives the formula for the prediction
of the number of hurricanes and tropical storms:
Correction Terms

\[
\begin{align*}
(\text{Predicted No. of Hurricanes and Tropical Storms per season}) &= \text{Ave.} + [\text{QBO} + \text{EN} + \text{SLPA} + \text{ZWA}] \\
&= \text{Ave. Season} + [\text{QBO} + \text{EN} + \text{SLPA} + \text{ZWA}] \\
\end{align*}
\] (2)

where

\[
\text{QBO} = 30 \text{ mb equatorial wind direction correction factor} \\
\text{EN} = \text{El Nino influence. If present subtract two for a moderate El Nino event, four for a strong El Nino event, otherwise add 0.7. If an indication of a weak El Nino event is present then subtract one.} \\
\text{SLPA} = \text{Same as for hurricane forecast.} \\
\text{ZWA} = \text{Same as for hurricane forecast.}
\]

c. Number of Hurricane Days

Equation (3) gives a prediction of the number of hurricane days per season,

\[
\begin{align*}
(\text{Predicted No. of Hurricane Days per season}) &= \text{Ave.} + [5 [(\text{QBO}_1 + \text{QBO}_2) + \text{EN} + \text{SLPA} + \text{ZWA})]] \\
&= \text{Ave. Season} + [5 [(\text{QBO}_1 + \text{QBO}_2) + \text{EN} + \text{SLPA} + \text{ZWA})]]
\end{align*}
\] (3)

where the meaning of the symbols are similar to Eq. 1 but each unit of correction factor will be multiplied by 5 instead of 1 as with the two previous determinations, thus

\[
\text{QBO}_1 = \text{QBO correction factor due to 30 mb wind direction - if westerly add one, if easterly subtract one. Set to zero if wind direction is in a change over phase from east to west or west to east during the season.}
\]
QBO \_2 = \text{QBO correction factor due to uniform change in 30 mb zonal wind (u) speed during the hurricane season} - \text{if increasing westerly (positive } \partial u / \partial t \text{) then add one, if decreasing westerly (negative } \partial u / \partial t \text{) then subtract one. Set to zero if there is a change of sign of } \partial u / \partial t \text{ during the season.}

\text{EN} = \text{If El Nino year then subtract two for moderate El Nino or four for a strong El Nino. Add one in all non-El Nino years.}

\text{SLPA} = \text{Same as for hurricane forecast.}

\text{ZWA} = \text{Zonal Wind Anomaly at 200 mb (12 km) for five low latitude upper air Caribbean stations. Valid for June and July wind data only in non-El Nino years. Used only to update the 1 August forecast. Not used for the 1 June forecast. Value +1 if mean June-July zonal wind anomaly for these 5 stations is less than -1 m/s. Value -1 if the same 5 station anomaly is greater than 1 m/s. Make zero if anomaly is } \leq 1 \text{ m/s.}

4. Assessment of Conditions

a. QBO Winds

Figure 5 shows the QBO equatorial stratospheric winds up through April of this year and the extrapolated wind values for the coming hurricane season. Note that in the coming 1987 hurricane season 30 mb QBO winds will be changing from the east to the west. The coming 1987 season will thus be one of 30 mb wind transition. This means that hurricane activity (other factors remaining normal) should not be increased or decreased due to this factor.

b. El Nino

A moderate intensity El Nino event began last autumn and has been in progress since that time. Figure 6 shows equatorial eastern and central Pacific sea surface temperature (SST) anomaly (°C) for the first 15 days of May. Note the broad area of positive temperature anomalies which are present. This El Nino event started much later in the year
Fig. 5. Vertical cross-section of recent stratosphere monthly average QBO west to east or zonal wind (in knots). This figure represents an average of the Balboa, C.Z. (9°N) and Ascension (8°S) rawinsondes. The climatological annual cycle has been removed from each sounding before averaging. Winds from a westerly direction have been shaded. Information beyond April 1987 has been extrapolated. Thick horizontal lines show the active portion of each hurricane season from 1984 to 1987.
Fig. 6. 1-15 May 1987 Sea Surface Temperature Anomaly (SST) in °C. Dotted areas show cold anomaly (-), unshaded areas positive anomaly (+) – from NOAA blended SST anomaly analyses.
than the typical El Nino. It reached a peak this winter and appears to be receding at this time. A question exists as to whether this El Nino event has any potential to experience a modest regeneration during this coming season. No one is sure just how many more months this current El Nino event will last. It appears to be in the dissipation stage however. Even if in a dissipation phase this El Nino event will likely affect the 1987 hurricane season. It is to be expected that there should be a slight reduction in Atlantic hurricane activity as a result of this present El Nino event. The author is consequently reducing his seasonal forecast of tropical cyclone activity by one hurricane, one name storm, and 5 hurricane days.

A better evaluation of the influence of this current El Nino event will be able to be made with the update of this forecast on 1 August.

c. Sea Level Pressure Anomaly (SLPA)

Table 1 gives information on 1 April–25 May, 1987 mean Caribbean–Gulf of Mexico SLPA in millibars (mb). Data is derived from six key stations of this region. The average of these stations is negative (−0.2 mb) but not negative enough (≤0.4 mb) that a correction for pressure be made.

d. Zonal Wind Anomaly (ZWA)

Value not applicable for 1 June forecast. Information from June–July data will be supplied for the updated 1 August forecast.

5. Seasonal Prediction for 1987

Table 2 gives the author’s numerical estimates of each term of his three prediction equations (1-3) for the 1986 season. The ZWA term is only used for the updated 1 August forecast and is thus non-applicable (N/A) to the 1 June forecast. Equations give correction factors to the average hurricane activity as measured over the last 40 years. Number of hurricanes, number of hurricanes and tropical storms, and number of hurricane days are forecast to be 5, 8, and 20 respectively.

**TABLE 2**

1987 Predicted Seasonal Hurricane Activity

\[
\text{Predicted No. of Hurricanes per Season} = \begin{array}{c} (QBO_1 + QBO_2) + EN + SLPA + ZWA \\ = 6 + (0) + (0) + (-1) + (0) + \text{N/A} = 5 \end{array}
\]

\[
\text{Predicted No. of Hurricanes and Tropical Storms per Season} = \begin{array}{c} 9 + QBO + EN + SLPA + ZWA \\ = 9 + (0) + (-1) + (0) + \text{N/A} = 8 \end{array}
\]

\[
\text{Predicted No. of Hurricane Days per Season} = \begin{array}{c} 25 + 5 [(QBO_1 + QBO_2) + EN + SLPA + ZWA] \\ = (0) + (0) + (-5) + (0) + \text{N/A} = 20 \end{array}
\]
The forecast for 1987 is thus for a slightly below average hurricane season based on hurricane season statistics of the last 40 years. If 1987 follows the average ratio of name storm days to hurricane days then one should expect about 40 named storm days.

Hurricane activity in 1987 should be more active than last year and more active than the recent 1982 and 1983 seasons. By the standard of the generally below average hurricane activity of 1970-1986 (Gray, 1987), 1987 is forecast to be about an average hurricane season.

Hurricane activity since 1970 has been reduced over that of average hurricane activity of the 23-year period of 1947-1969. This is especially the case with regards to low latitude and intense hurricane activity caused by tropical disturbances of west African origin. This reduction of low latitude Atlantic hurricane activity since 1970 is associated with the multi-decade African Sahel draught conditions of the 1970's and 1980's and the generally higher summertime Caribbean basin surface pressures and stronger Caribbean basin 200 mb (12 km) west zonal winds which have occurred during the last 15-17 years. It is impossible to tell how many more years these generally suppressed Atlantic hurricane conditions will last.
6. Cautionary Note

It is important that the reader realize that the author's forecast scheme, although showing quite promising statistical skill in the typically meteorological sense, can only predict about 50% of the total variability in Atlantic Seasonal hurricane activity. This forecast scheme will likely fail in some years when the other unknown factors (besides the QBO, EN, SLPA and ZWA) which cause storm variability are more dominant, or, if the QBO or EN conditions should be misforecast. It is impossible to determine beforehand in which years the author's forecast scheme will work best or worst.

This forecast scheme cannot be judged in its verification in any one or a few seasons. The author is very confident that this forecast scheme has definite skill over a longer time period of 10-12 seasons. It should only be evaluated on this longer time scale.

This forecast scheme also does not specifically predict which portion of the hurricane season will be most active or where within the Atlantic basin the storms will strike. For instance, 1981 was a moderately active season (7 hurricanes, 12 hurricanes and tropical cyclones) but only two of the weaker systems affected the US. By contrast 1985 had a similar amount of overall hurricane activity as 1981 did, but 1985 had 6 hurricanes and 8 named storms affect the US coastline. 1983 was one of the most inactive seasons on record but Hurricane Alicia caused over a billion dollars of damage to the Houston area. If there is only one Atlantic hurricane this year, but it happens to go over your house or business, then for you, 1987 will seem to be a very active hurricane season indeed!
7. Verification of Author’s 1984, 1985, and 1986 Seasonal Forecasts

Tables 3-5 give verification information on the author’s 1984 through 1986 seasonal predictions. In 1984 hurricane activity was over predicted but the total of hurricane and tropical storm activity underpredicted. The 1985 and 1986 forecasts were closely verified.

8. Acknowledgements

The author is grateful to the following meteorologists for the information furnished to him and/or beneficial discussions on: 1) the characteristics of the stratospheric QBO from James Angell and Keith Johnson of NOAA; 2) on the El Nino by Vernon Kousky (NOAA Climate Analysis Center), and James O'Brien of Florida State University, and general opinions coming off of the ENSO.INFO telemail circuit.

The author also thanks Arthur Pike of NOAA and Lexion Avila of the University of Miami for supplying him with Caribbean Basin springtime sea level pressure and upper air wind information.

The author would also like to acknowledge the very beneficial encouragement he has received for this type of forecasting research and application from Neil Frank and Robert Sheets, former and current Directors of the National Hurricane Center and other forecasters at the center.

This research has been funded by the National Science Foundation.
9. Bibliography

Author - The author of this paper is a Professor in the Dept. of Atmospheric Science at Colorado State University.
